Fig. 1: Tin bronze sheet fragment (section and front side) (after Department of Prehistory, University of Zurich),

⌄ Description and visual observation

|	
Description of the artefact	Sheet fragment with a dark green and grey powdery surface (patina) that might have been caused by exposure to high temperatures. A green layer appears below the dark surface. Dimensions: L = 2.4cm; W = 2.3cm; WT = 4.8g.
Type of artefact	Metal sheet
Origin	Ritual place Wartau Ochsenberg, Sankt Gallen, Saint Gallen, Switzerland
Recovering date	Excavation in 1991
Chronology category	Iron Age
chronology tpq	500 B.C. ⌄
chronology taq	401 B.C. ⌄
Chronology comment	5th Century BC
Burial conditions / environment	Soil
Artefact location	Kantonsarchäologie, Sankt Gallen, Saint Gallen
Owner	Kantonsarchäologie, Sankt Gallen, Saint Gallen
Inv. number	WT10-M305
Recorded conservation data	Not conserved

Study area(s)

Fig. 2: Location of sampling area,

Binocular observation and representation of the corrosion structure

Stratigraphic representation: none

MiCorr stratigraphy(ies) – Bi

Sample(s)

Fig. 3: Micrograph of the cross-section showing locations of the Figures 4, 5, 7 and 8,

Description of sample	The sample is a section from the top right corner of the sheet (Fig. 2). Its dimensions are: L = 2.5mm and W = 2.3mm. The metal is surrounded on three sides by corrosion products. Intergranular corrosion has developed throughout the metal section (Fig. 3).
Alloy	Tin Bronze
Technology	Secondary recrystallization (produced by burning) after cold working
Lab number of sample	MAH 92-5-2-003
Sample location	Musées d'art et d'histoire, Genève, Geneva
Responsible institution	Musées d'art et d'histoire, Genève, Geneva
Date and aim of sampling	1992, examination of the corrosion layer

Analyses and results

Analyses performed:
Metallography (etched with ferric chloride reagent), Vickers hardness testing, ICP-OES, SEM/EDX, Raman spectroscopy.

⌄ Non invasive analysis

⌄ Metal

The remaining metal is a porous (red arrows on Fig. 4) tin bronze (Table 1). Five analyses were made, including S in non-corroded metal (2 measurements), and P (3 measurements) in partially corroded metal. As no major difference in the composition was observed (comparison of RSD) all analyses were used to calculate the median value. Inter- and transgranular corrosion has developed so extensively that all grain boundaries and twin lines are outlined (Fig. 4). After etching, we observe annealed polygonal grains with a few twins and slip lines below the surface (Fig. 5). The slip lines are restricted to the right side of the sample where the metal is best preserved (Fig. 5). The grain size varies between 50 and 170μm, due to an excessively long or hot annealing procedure leading to a grain coarsening. Small copper sulphide inclusions appear in blue. The average hardness of the metal is HV1 90.

Microstructure	Large polygonal grains with few twins + strain lines
First metal element	Cu
Other metal elements	Sn

⌄ Corrosion layers

The corrosion crust varies in thickness between 60 and 150µm (Fig. 3). In bright field, it appears dark-grey (Fig. 4) and consists of two layers. The inner layer is dark-grey and dense while the thin outer layer is slightly lighter coloured. Within the metal, the corrosion products are light-grey (Fig. 4). Under polarized light, the corrosion layer turns blue-green with dark-blue areas (Figs. 6 and 7) whereas corrosion products inside the metal are either light-blue (Figs. 6 and 7) or red-orange (Figs. 6 and 7). The red corrosion products have the composition of cuprite/Cu_2O while the orange compounds are enriched in Sn (Table 2). The blue-green corrosion products both within the remaining metal and on the surface are even richer in Sn and O, and contain some P (Table 2 and Fig. 8). The thin, irregular dark-grey surface layer is enriched in P, Fe, Si and Al (Table 2 and Fig. 8). XRD analyses of powdery particles sampled from the thin, dark surface corrosion layer indicate the presence of tenorite/CuO and cassiterite/SnO_2 (Museum report 1992). The Raman spectra of this layer (Fig. 9) confirmed the presence of tenorite.

Elements	O	Cu	Sn	Si	Fe	P	As	Total

Corrosion form	Uniform - intergranular
Corrosion type	Mostly type II with locally type I (Robbiola)

⌄ MiCorr stratigraphy(ies) – CS

Fig. 4: Stratigraphic representation of the object in cross-section using the MiCorr application. This representation can be compared to Fig. 7.

⌄ Synthesis of the binocular / cross-section examination of the corrosion structure

Corrected stratigraphic representation: none

⌄ Conclusion

The tin bronze sheet shows traces of cold working but has been exposed to an extended or excessively hot annealing process. According to Northover (Northover in preparation), the relative lack of twins and their large size confirm a prolonged annealing process. Furthermore large grains, large twins and extensive intergranular corrosion are characteristic of objects that have been exposed to a hot reducing flame either in a house fire or on a funeral pyre. All corrosion products except the cuprite are Sn enriched. The enrichment in P of the surface layer might be due to an environment rich in organic material (for example bones). Tenorite analysed by XRD and Raman spectroscopy is very rare in ancient Cu corrosion and must be interpreted as a further tracer for Cu corrosion in burning context. The original surface of the metal has been destroyed resulting in a type 2 corrosion layer after Robbiola et al. 1998. Only locally in the areas where tenorite is preserved does type 1 patina occur.
