## ✧ Description and visual observation

<b>Description of the artefact</b>	Fragment from a series of 9 elements of a Roman bed structure, covered with green-black corrosion products (Fig. 1).
<b>Type of artefact</b>	Furniture element
<b>Origin</b>	"Palais de Derrière la Tour", Avenches, Vaud, Switzerland
<b>Recovering date</b>	Excavation 2003
<b>Chronology category</b>	Roman Times
<b>chronology tpq</b>	150 A.D. ▼
<b>chronology taq</b>	200 A.D. ▼
<b>Chronology comment</b>	Second half of the 2nd Century AD
<b>Burial conditions / environment</b>	Soil

Artefact location	Roman museum, Avenches, Vaud
Owner	Roman museum, Avenches, Vaud
Inv. number	03/12751-20.2.5
Recorded conservation data	N/A

#### Complementary information

The metal underneath the green-black corrosion layers is decorated with incrustations (Ag and Cu) representing meanders and olive branches. An intentional black patina might have been applied on the ancient surface to contrast it with the silver and pink coloured inlays.

#### Study area(s)

#### Sample(s)

Fig. 3: Micrograph, in bright field, of the cross-section of the sample taken from the bed structure showing the location of Figs. 4 to 8,

Credit HE-Arc CR.

<b>Description of sample</b>	The sample is a section from the fragment represented on Fig. 2. The remaining metal is surrounded by a thick corrosion crust (Fig. 3). Its dimensions are: L = 3.5mm and W = 1.5mm.
<b>Alloy</b>	Tin Bronze
<b>Technology</b>	Partly annealed after cold working
<b>Lab number of sample</b>	HECR-MK5
<b>Sample location</b>	HE-Arc CR, La Chaux-de-Fonds, Neuchâtel
<b>Responsible institution</b>	HE-Arc CR, La Chaux-de-Fonds, Neuchâtel
<b>Date and aim of sampling</b>	2008-2009, analyses of the corrosion products

#### Complementary information

None.

#### ✧ Analyses and results

##### *Analyses performed:*

Metallography (etched with ferric chloride reagent), Vickers hardness testing, SEM/EDS, XRD, Raman spectroscopy.

#### ✧ Non invasive analysis

None.

#### ✧ Metal

The remaining metal is a porous tin bronze (Table 1) with tiny iron oxides inclusions (Table 2) and secondary re-deposited copper. Intergranular corrosion has developed locally inside the metal (Figs. 4 and 5). The etched alloy

shows a structure principally consisting of large polygonal grains, some of which include strain lines (Fig. 6). Locally an isolated alpha + delta eutectoid can be seen. Much smaller twinned grains can be found on the left side of the sample (Fig. 5). The average hardness of the metal is HV1 100. However on the left side of the sample, where the grains are smaller and twinned, the hardness is much higher (more cold work followed by annealing).

None.

#### Corrosion layers

The metal - corrosion products interface is irregular (Fig. 3) and the average thickness of the corrosion crust is 300μm. The latter can be divided into four layers (Fig. 4). In bright field, the inner layer (CP4) is medium grey and dense. In polarised light it is dark-red/orange (Fig. 7). It is Sn-rich, contains O and Cl but is Cu depleted (Table 3 and Fig. 8). The next layer (CP3) is as well medium grey in bright field and light-red in polarised light. It has a composition similar to cuprite/Cu<sub>2</sub>O (Table 3). This was confirmed by Raman spectroscopy (Fig. 9). The third layer (CP2) is thin, is light grey in bright field and contains black pores. Under polarised light it looks brilliant black (Fig. 7) and is rich in Cu with Sn and O (Fig. 8). Using XRD, it was identified as a mixture of tenorite/CuO, cuprite/Cu<sub>2</sub>O and cassiterite/SnO<sub>2</sub> (Krieg 2009). Raman spectroscopy could only detect tenorite in this layer (Fig. 10). In bright field the thick outer layer (CP1) is marbled in dark-grey and black, in polarised light it appears blue-green (Fig. 7). XRD analysis gave a composition close to malachite/Cu<sub>2</sub>CO<sub>3</sub>(OH)<sub>2</sub> (Krieg 2009). In the present study no C was detected (Fig. 8), but Raman spectroscopy confirmed its presence (Fig. 11). The spectrum obtained shows a good match with published spectra (Bouchard and Smith 2003). Peaks are similar to those expected for malachite but most of them have a Raman shift: 3322, 1503, 1108, 1073, 759, 731, 603, 540, 442, 357, 276, 225, 186, 163 cm<sup>-1</sup>. The underlined Raman shifts correspond to the peaks of greatest intensity. Environmental elements such as Si are concentrated on the top surface (Fig. 8).

Elements	O	Cu	Sn	Si	Cl	Mn	Fe	Pb	Total
CP3, red outer edge of the inner corrosion layer (average of 2 similar analyses)	19	69	5.1	0.7	<	<	<	<	94
CP4, dark-orange inner corrosion layer (average of 3 similar analyses)	25	52	25	0.9	0.6	<	<	1.0	104

## ✧ Conclusion

One side of the tin bronze artefact has been repeatedly annealed after cold working whereas the rest of the metal was cold worked. The metal is covered with a terrestrial type corrosion layer. Cl is found in proximity to the metal in a Sn-rich but Cu-depleted inner area of the first cuprite layer. It is followed by an intermediate thin layer composed of a mixture of tenorite and tin oxides. The third voluminous layer is malachite. These results confirm Krieg's conclusions (Krieg 2009). Since the bed fragments have been excavated from a burnt down house, it is difficult to judge if the tenorite is an intentional black patina or if it is the result of heating during the fire. The limit of the original surface is outlined by the clear demarcation of Sn content (internal marker) in the first two corrosion layers and can be located between layers 2 & 3. Intentional or no, the black tenorite/cassiterite layer most likely represents the surface that will retain most surface details. In this case, the corrosion type is difficult to attribute after Robbiola et al. 1998.
